## REPORT OF COOPERATIVE RESEARCH ON INSECT CONTROL IN FARM STORED GRAIN

No. 14. Period--October 1 to December 31, 1944

Compiled by R. T. Cotton, Entomologist
Cereal and Forage Insect Investigations
Bureau of Entomology and Plant Quarantine
U. S. Department of Agriculture
Manhattan, Kansas

The material in this report consists largely of unpublished data and should be kept confidential. It is made available in its present form for the convenience of the various State and Federal Agencies concerned with the preservation of stored grain from insect damage.

## WHEAT STORAGE

Observations on the Insect Populations in Wheat-Stored Under Different Systems of Management\*

During December, average samples were taken from the bins remaining in the management series on the Hutchinson Experimental Wheat Storage site. These samples consisted of one quart (approx. 1,000 grams) of wheat taken from the center, north, east, south, and west quadrants of the bins. Five one-quart samples were taken from 1,000-bushel bins and ten one-quart samples from 2,740-bushel bins. The insect population was determined by sifting the individual quart samples and recording the number and kind of insects in each of them. In this manner the location and degree of infestation was determined for each bin together with the average for the bin. The results are given in table 1. It is of interest to note the low level of insect populations in the "Fumigation in September" series which is fumigated with carbon tetrachloride at a dosage of only 2 gallons per 1,000 bushels.

<sup>\* --</sup> Reported by H. H. Walkden and R. B. Schwitzgebel, U. S. Dept. of Agriculture, Bureau of Entomology and Plant Quarantine in cooperation with the Bureau of Plant Industry, Soils, and Engineering.

Study of the Fluctuation of Insect Populations in Wheat Stored in Ever-Normal Granary Type Bins

The study of insect population fluctuations in wheat stored in ever-normal granary type bins was continued during the past quarter. Five-probe samples were taken from the upper southwest quadrant of 36 bins in the Management Series and a record made of the number of each species of stored grain insects. A summary of the data obtained during the past nine months is presented in table 3 and arranged to show the effect of different grain storage practices on insect populations.

For the purpose of this table the lesser grain borers and rice weevils were considered "weevils" and all other species were combined as "bran bugs". Rice weevils were rarely taken and the flat grain beetle, sawtoothed grain beetle and longheaded flour beetle were the principal bran bugs.

The only untreated grain which failed to develop serious insect populations throughout the entire season was the 9-10 per cent moisture wheat in unpainted bins and also all grain stored in bins with white walls and roofs. The lesser grain borer populations were especially low in these bins. The other grain storage practices -- fumigation in August and October; fumigation in September; and turning, cleaning and fumigation in September -- reduced the insect populations to a very low level so that the grain entered the winter season in good condition.

As shown by the data of table 3 fumigation in August and October kept the infestation at a lower level during the entire season than either fumigation in September or turning, cleaning, and fumigation in September. It should be noted, however, that bins fumigated in September were treated with a dosage of 2 gallons of carbon tetrachloride per 1,000 bushels, which is not equivalent to the 4 gallon dosage of the 3-1 mixture of ethylene dichloride and carbon tetrachloride applied to the bins fumigated in August and October.

Table 3: -- Summary of the insect populations in the upper southwest quadrant of steel and wood bins, which in son, Kansas, 1944.

Study of the Migration of Stored Grain Insects by Means of Bin Ventilator Traps

During the past season bin ventilator traps were employed to study the migration of stored grain insects into a galvanized bin and a bin painted white. The bins were tightly calked to prevent the entrance of insects except through the ventilators which were fitted with traps to retain the insects entering in this manner. The traps were in operation from July 3 to November 13. The catches were examined at weekly intervals throughout the season and the results are summarized in tables 4 and 5.

A total of 1353 insects were taken in the two traps during the season with more than 75 per cent of the catch taken in the unpainted bin. Large catches were recorded from the last of July through October in this unpainted bin whereas over half the total catch for the white bin occurred in August. Probably the most significant fact in this study was that more than thirty times as many lesser grain borers migrated into the unpainted bin than were taken in the trap in the bin which was painted white. This species has continued to be the most serious stored grain pest at the Hutchinson site since its erection in 1941. Any measure to prevent or to reduce the activity of this pest is of high importance in the storing of grain in southern Kansas, Oklahoma, and Texas.

## control of Insects in Farm Stored Grain

various interior wall treatments have been applied in farm bins and have been discussed in Reports 12 and 13. During November the bins were sampled to determine the kind and degree of insect infestation, and in the more heavily infested bins estimates of the amount of damage to the grain were made. The infestation in the different bins is summarized in table 6. It may be noted that the greatest number of dead insects was found near the walls treated with DDT.

The cadelle (Tenebroides mauritanious L.) was the most abundant species found in farm bins during November. The most intense infestation was found in the west bin on the Oldenettel farm. Quart samples were taken just below the surface next to the walls in this bin. Sub-samples were cut from these and the number and weight of insect-damaged kernels were determined.

The results are given in table 7. The wheat was of the 1944 crop and the bin was filled at harvest late in June, 1944. It may be noted from the table that about 4 per cent of the wheat in the center of the bin has sustained damage after about 5 months of storage. Next to the walls, on a weight basis, the damage ranged from about 4 per cent to more than 7 per cent. It should be borne in mind that the above figures represent the most extreme case observed thus far, and the damage is much less in the majority of farm bins.

#### Experimental Fumigation of Wheat

During the past quarter a total of 27 bins, aggregating nearly 36,000 bushels of wheat, have been fumigated experimentally. The majority of the bins were located on the farm, and were made available through the cooperation of Reno County farmers. The results of the experimental fumigation work are given in table 8, parts 1 (steel bins), and 2, (wooden bins).

part 1. Experimental Fumigation of Wheat Stored in Steel Bins. (Table 8, part 1.)

Using a dosage of 2 gallons of carbon tetrachloride per 1,000 bushels as a check, methylene chloride, trichloroethylene, tetrachlorethane, and a 3:1 mixture of ethylene dichloride and carbon tetrachloride failed to give satisfactory kills at the dosages used in these experiments except in one bin, (5-8).

part 2. Experimental Fumigation of Wheat Stored in Wooden Ever-Normal Granary Bins and Wooden Farm Granaries. (Table 8. part 2.)

Due to the great differences in the construction and tightness of farm granaries, it is difficult to make comparisons of the effectiveness of various fumigants. However, from the data given in table 8, part 2, it would appear that a mixture of carbon tetrachloride, 90 per cent and ethylene dibromide, 10 per cent, is an effective fumigant for farm scored grain at dosages of 2 to 4 gallons per 1,000 bushels, depending on the tightness of the granary. (The ethylene dibromide used in this work was supplied through the cooperation of the Dow Chemical Company).

The role of ethylene dibromide is that of a surface toxicant. In steel bins it is unusual to find a heavy surface infestation and so carbon tetrachloride is an effective fumigant when used alone. However, in wooden granaries cadelles are usually found in the surface grain and near the walls. Under such conditions carbon tetrachloride failed to give complete kills of the cadelles. The mixture of 10 per cent ethylene dibromide and 90 per cent carbon tetrachloride effected nearly perfect kills of all species under these conditions.

#### Rate of Penetration of Fumigants in Stored Wheat

During the past quarter, further observations were made on the rate of penetration of fumigants in wheat stored in steel bins, in wooden Ever-normal Granary bins, and also in wooden farm granaries. The rate of penetration of the gas was determined by placing test probes containing living insects in the grain. A sufficient number of probes were put in the grain so that one probe could be withdrawn at one-hour intervals after fumigation and the insect mortality determined at various levels, until the maximum kill had been effected.

Six compounds and mixtures were used. The rate of penetration, as evidenced by mortality at various levels, are given in table 9.

In general, the results indicate that in tight bins the vapors of the fumigants used in these tests reach the bottom of the bin within 3 to 4 hours after application to the grain surface. However, in loosely constructed wooden bins, with grain surfaces exposed to outside air currents, the gas may be dissipated before a lethal concentration can be attained in any or all parts of the grain mass.

Effect of Magnesium Oxide, Almicide, and DDT on the Germination of Wheat\*

In order to test the effect of the long time exposure of wheat to magnesium oxide, Almicide, and DDT, a series of tests using 12, 14, and 16 per cent moisture wheats were set up.

Seven months have elapsed since these tests were started. Table 10 summarizes the results of monthly germination tests.

Twelve per cent moisture wheat shows no loss in germination when treated with dosages, of either of the three chemicals, sufficiently high to insure protection against insect attack.

Fourteen per cent moisture wheat shows some loss in germination, but in most cases this loss is negligible, and when compared with the 14% moisture check, all three chemicals give indications of having some germicidal value.

Table 10: -- Effect of chemical dusts on the germination of wheat.

<sup>\* -</sup> Reported by J. C. Frankenfeld.

#### Magnesium Oxide for Seed Treatment\*

In previous tests described in Report No. 12, pages 22-25, it was shown that magnesium oxide, with a surface-mean particle diameter of less than 0.25 micron, gave excellent protection to seed from insect attack when mixed with seed at the rate of 0.1 per cent by weight or more. In view of the work of British scientists with inert dusts which indicated that particle size was closely correlated with insecticidal properties, it seemed desirable to experiment with various commercial samples of magnesium oxide to determine whether or not there were any great differences in their insecticidal efficiency.

With the assistance of Dr. R. C. Roark, Chief of the Division of Insecticide Investigations, and various chemical companies, a representative number of magnesium oxide and related dusts were assembled and tested under laboratory conditions, to determine their relative efficiency in protecting wheat seed from the attack of the rice weevil. The rice weevil was chosen as the test insect since the immature stages are concealed within the seed and are not subject to the action of the dust. This feature makes it more difficult to control with dusts than free-living species of grain infesting insects.

Tests were conducted at room temperature, 70° to 75° F., with wheat of 12 per cent moisture content.

Five hundred-gram samples in duplicate were treated with each dust at the rate of .05 per cent and 7.1 per cent by weight and infested with 100 rice weevil adults. Observations were made at weekly intervals until a complete mortality of the insects was obtained or the treatment was found to be ineffective. The results of these examinations are given in tables 11 and 12.

<sup>\*-</sup>Reported by R. T. Cotton and J. C. Frankenfeld.

Table 11:--Insecticidal action of magnesium oxides and other dusts against the rice weevil in seed wheat of 12% moisture content. 500-gram lots of seed treated at rate of 0.5% by weight and infested with 100 rice weevil adults.

G. M. & M. - General Magnesite and Megnesia Co. ... Keasty and Mattison Co.

From the data of tables 11 and 12, it is evident that a wide range of commercial grades of magnesium oxide are effective in protecting seed wheat from the attack of the rice weevil when used at the rate of 0.1 per cent by weight. A dosage of 0.05 per cent by weight, although effective in killing the adult weevils, did not kill them rapidly enough to prevent some reproduction. In general, the magnesium oxides with a surface-mean diameter particle size of less than 1 micron were the most effective and afforded satisfactory protection at the .1 per cent by weight dosage.

The cost of these materials varied from  $2\frac{1}{2}$  cents per pound to \$2.25 per pound with many of the cheaper compounds being just as effective as the more expensive ones.

Voluminosity, while important, did not appear to be directly correlated with efficiency, e.g., Golwynne's Shamva heavy calcined magnesia tech. with a voluminosity of 60 cubic inches per pound killed as rapidly as Keasby and Mattison's light calcined magnesia with a voluminosity of 470 cubic inches per pound and slightly more rapidly than G. M. & M. extra light calcined magnesia with a voluminosity of 660 cubic inches per pound.

Tests have been started with Michigan #15 heavy calcined magnesia to determine its effectiveness against insects other than the rice weevil. This material was chosen on account of its low cost. Results of these tests with the confused flour beetle and the cadelle are given in table 13.

Table 13: -- Insecticidal action of Michigan #15 heavy calcined magnesia against the confused flour beetle and the cadelle. 500-gram samples of 12% moisture wheat infested with 100 adult flour beetles or 25 cadelle larvae.

From the data of table 13 it is evident that the magnesium oxide did not kill the flour beetle adults or the cadelle larvae as rapidly as the rice weevil. However, no reproduction of these free-living species occurred so that it is logical to assume a dosage of .1% by weight would eventually destroy infestations of these species that might be in the seed and would protect the seed from further infestation.

#### Field Tests

Field tests with inert and chemical dusts are now underway at the Ft. Hays Experiment station, Hays; Kansas. Large quantities of high grade sorghum, wheat, barley, and bat seed were available for treatment and seed was treated in bushel lots, resacked in cotton bags and placed in the seed warehouse of the experiment station. The longtime storage of this seed will provide a real test of the efficiency of dusts in protecting seed from insect damage. In addition to the Michigan #15 heavy calcined magnesia, DDT in combination with this material, pyrophyllite and micro mag\* to make a 3 per cent mixture was included for comparative purposes. Treatments given the various seeds are listed below.

#### Effect of Fumigation on Baking Quality

In connection with our experimental work on the effect of fumigants on the germination and baking quality of wheat which was summarized in Report No. 13, pages 24 to 28, it is of interest to record data obtained on changes in fat acidity and baking values of wheat stored at Jamestown, North Dakota. One series of 9 bins received an annual fumigation with a 3-1 mixture of ethylene dichloride and carbon tetrachloride, plus 10% methyl bromide, at a dosage of 2 gallons per 1,000 bushels. Another similar series received no treatment. Samples of wheat for baking tests, fat acidity tests, and germination tests, were taken from all bins at the time of the annual fumigation for the years 1941, 1942, and 1943.

In the fumigated series an average loss of viability of more than 50 percent occurred over the 3-year period whereas in the unfumigated series the average loss in viability was less than 10 per cent.

Changes in fat acidity and baking values of the wheat in the two series of bins are indicated in tables 14 and 15.

The data of tables 14 and 15 indicate little difference between the various lots of wheat with respect to changes in baking values and fat acidity regardless of whether or not the wheat was fumigated or whether the germination was reduced as a result of fumigation. When baked by Method No. 2 most wheats showed a gradual loss in loaf volume over a 3-year period, whereas when baked by Method 3a, a general increase in loaf volume resulted. This agrees well with the results of our experimental work summarized in Report No. 13.

<sup>\* -</sup> Data from U. S. D. A. Baking and Milling Laboratory, Washington, D. C.

Effect of Temperature and the Moisture Content of Wheat Upon the Survival and Reproduction of the Granary and Rice Weevils

On pages 35 and 37 of Report No. 13 we discussed the effect of temperature and grain moisture on the granary and rice weevils when held at a constant temperature of 60° F. At the time that report was prepared this series of tests had been in operation for 13 weeks. The work herewith reported is a continuation of the above described tests. In table 16 is listed the percentage of survival of adult weevils at the end of 15, 17, and 19 weeks. As was indicated in the previous report, the percentage of survival of both the granary and rice weevil increases as the moisture content of the wheat is increased. In the 9% moisture wheat there was only a very small percentage of survival in the case of the rice weevil after the first week. By the end of the 13th week all adults had died.

Although a comparatively high survival of the granary weevil is noted, reproduction by this species at 60° F. is very light, and then only in the 12, 13, and 14% moisture wheats. In the case of the rice weevil, no reproduction occurred in the 9 and 10% wheats; a small amount in the 11 and 12% wheats; and a fairly heavy reproduction in the 13 and 14% wheats. With both species the tendency, even at a temperature of 60° F., is for increased reproduction as the moisture content of the wheat is increased. See tables 17 and 18.

It is interesting to note that in the case of the granary weevil no reproduction occurred until the 10 and 11th weeks. This delayed reproduction on the part of the granary weevil was likewise observed in the tests conducted at a constant temperature of 65° F.

Since both the granary and rice weevil reproduced at 60° F., our investigations were continued by reducing the temperature to 55° F., using the same moisture variants. This new series of tests has been in progress for seven weeks, and the results of biweekly examination are listed in table 19. Again, as in the tests conducted at a constant temperature of 60° F. the percentage of survival increases as the moisture content of the wheat is increased. A higher percentage of survival at each moisture variant is noted for the granary weevil as compared to the rice weevil.

No reproduction at any moisture level for either the granary or rice weevil has been obtained to date.

Table 16: -- Percentage of survival of the granary and rice weevil at 60° F: in wheat of various moisture content.

Effect of Temperature, Moisture, and Dockage on the Survival and Reproduction of T. castaneun

On pages 30-32 of Report No. 13, are given the results of the effect of grain moisture and dockage on T. Castaneun when held at a constant temperature of 90° F. for eight wooks. These tests were continued and completed during the interim of this report. For convenience the weekly record of survival for the series for the first 8 weeks is repeated in table 20, together with the record of the final eleven weeks. It will be noted that as the moisture content of the wheat is increased an increase in survival results. And to a certain extent, for a given moisture content, the percentage of survival increases as the percentage of dockage is increased. This is more pronounced in the lower moisture level wheat. In 15% moisture wheat there is no significant difference in the percentage for the different moisture variant lots.

In table 21 is summarized the weekly recovery of pupae of T. castaneum from the above discussed lots. It will be noted that in general there is a definite increase in the total number of pupae recovered as the moisture content of the wheat and the amount of dockage is increased. The decrease in reproduction in the 15% moisture series, as compared to the 12% series, is probably due to the development of molds which is frequently encountered in wheat with a high moisture content. Those molds are very injurious to the eggs of the flour beetles.

It is interesting to note that reproduction at 90° F. is heaviest during the first three or four weeks. (The time required for development from egg to pupa is between 3 - 4 weeks at 90° F.) After about the 7th week egg laying is practically discontinued in most lets. Just what the cause for this unexpected cessation of reproduction, so early in the life of the adult, is as yet unexplainable.

In another series of tests conducted at a constant temperature of 85° F., table 22, we find practically the same general relationship as in the 90° F, series. Survival and reproduction increase as the moisture content of the wheat is increased, and in the lower moisture level wheat as the dockage is increased.

A more uniform reproduction increase (table 23) with the increase in moisture and dockage occurs at this temperature than at 90° F. However, the total reproduction, lot for lot; is considerably smaller in the 85° F. series. Here again we find that reproduction is confined to the early part of the life of the adult, discontinuing entirely in practically all lots after the tenth week.

In conjunction with the tests on the effect of temperature, moisture, and dockage on the survival and reproduction of T. castaneum accurate records were kept on the length of larval development.

For these records, eggs were sifted from flour infested with adult T. castaneum. These eggs were maintained at a constant temperature of 80° F. until hatched. Newly hatched larvae were then confined in small shell vials with whole wheat flour and placed in incubators at 85° F. and 90° F.

At 85° F. an average of 24.4 days are spent in the larval stage, ranging with individual specimens from 23 to 27 days. At 90° F. an average of 22.5 days are spent in the larval stage, ranging from 20.8 to 23.6 days, showing a reduction of approximately 2 days in the developmental period at 90° F. as compared with the developmental period of 85° F.
